ABSTRACT

Fiber-Reinforced Concrete (FRC) has emerged as an advanced construction material capable of enhancing the mechanical performance and durability of conventional concrete. The incorporation of discrete fibers improves tensile strength, crack resistance, ductility, and energy absorption capacity. This study investigates the mechanical behavior of fiber-reinforced concrete designed for high-performance structural applications. Steel and polypropylene fibers were incorporated in varying volume fractions to evaluate their influence on compressive, split tensile, and flexural strength. Experimental analysis was conducted through standard mechanical testing procedures. The results indicate significant improvement in tensile and flexural strength with increasing fiber content. Crack propagation was effectively controlled due to fiber bridging mechanisms. The study demonstrates that FRC exhibits enhanced post-cracking behavior and improved structural integrity. The findings confirm its suitability for high-load and seismic-prone structures. The research contributes to understanding optimized fiber dosage for performance enhancement.

Keywords

Fiber-Reinforced Concrete, High-Performance Concrete, Mechanical Properties, Compressive Strength, Flexural Strength, Crack Resistance, Ductility.

I. INTRODUCTION

Concrete is one of the most widely used construction materials worldwide due to its versatility and cost-effectiveness. However, conventional concrete exhibits low tensile

strength and brittle failure behavior, limiting its performance under dynamic and high-load conditions. To overcome these limitations, fibers are introduced into the concrete matrix to improve its mechanical characteristics. Fiber reinforcement enhances ductility, toughness, and crack resistance, thereby increasing structural reliability. The growing demand for high-performance concrete in modern infrastructure projects has intensified research in this field.

Fiber-reinforced concrete incorporates discrete fibers such as steel, glass, polypropylene, or hybrid combinations into the cementitious matrix. These fibers act as crack arrestors, bridging micro-cracks and preventing their propagation. The inclusion of fibers modifies the stress distribution within the concrete and enhances post-cracking behavior. In high-performance applications such as bridges, tunnels, pavements, and high-rise buildings, improved tensile capacity and impact resistance are critical. Therefore, understanding the mechanical behavior of FRC becomes essential for safe structural design.

High-performance concrete (HPC) requires superior strength, durability, and long-term stability. Traditional HPC improves compressive strength but does not adequately address tensile weaknesses. Fiber reinforcement compensates for this drawback by enhancing flexural and tensile properties. The mechanical performance of FRC depends on fiber type, aspect ratio, orientation, and volume fraction. Optimizing these parameters is necessary to achieve balanced mechanical properties without compromising workability.

The incorporation of fibers also improves energy absorption and impact resistance. This makes FRC suitable for seismic zones and industrial floors subjected to heavy loads. Moreover, fibers reduce shrinkage cracking and improve fatigue performance. With increasing urbanization and infrastructure development, the need for sustainable and durable construction materials has become more pronounced.

This study focuses on evaluating the mechanical behavior of fiber-reinforced concrete intended for high-performance structural applications. The research aims to analyze compressive, tensile, and flexural properties under varying fiber contents. The findings contribute to optimized material design for advanced construction systems.

II. LITERATURE REVIEW

Early research on fiber reinforcement demonstrated significant improvements in concrete toughness and crack resistance. Romualdi and Batson (1963) investigated steel fiber reinforcement and observed enhanced tensile capacity. Subsequent studies established that fibers improve post-cracking performance by distributing stresses across the matrix. Researchers emphasized that fiber bridging mechanisms play a critical role in preventing sudden brittle failure.

Bentur and Mindess (1990) provided comprehensive insights into the material properties and behavior of fiber-reinforced cement composites. Their work highlighted the importance of fiber-matrix interaction in determining mechanical performance. Later studies examined the influence of fiber geometry and dosage on strength characteristics. It was found that higher aspect ratios improved tensile properties but reduced workability.

Banthia and Trottier (1994) studied crack control in FRC and reported improved durability performance. They concluded that fibers

significantly reduce crack width and improve resistance against environmental degradation. Naaman (2003) further analyzed strain-hardening behavior in high-performance fiber-reinforced cementitious composites. His work demonstrated improved ductility and energy absorption capacity.

Recent research prior to 2018 focused on hybrid fiber systems combining steel and synthetic fibers. These studies indicated synergistic effects leading to enhanced mechanical properties. Hybrid systems improved impact resistance and fatigue life compared to mono-fiber systems. The literature suggests that optimized fiber content is crucial for achieving maximum performance gains.

Despite extensive research, variations in testing procedures and material composition create inconsistencies in reported results. Therefore, systematic experimental investigation is necessary to determine optimal fiber dosage for high-performance applications. This study builds upon previous findings to evaluate mechanical behavior under controlled experimental conditions.

III. PROPOSED METHODOLOGY

The research methodology involves experimental investigation of fiber-reinforced concrete mixes with varying fiber contents. Ordinary Portland Cement, fine aggregates, coarse aggregates, and potable water were used to prepare control and fiber-reinforced mixes. Steel and polypropylene fibers were added at volume fractions of 0.5%, 1.0%, and 1.5%.

Concrete specimens were cast in standard molds for compressive, split tensile, and flexural strength testing. Proper mixing procedures were followed to ensure uniform fiber distribution. The mix design was developed according to standard guidelines for high-performance concrete.

Workability tests were conducted using slump cone apparatus. Mechanical testing was performed after 7 and 28 days of curing. Compressive strength tests were conducted using a universal testing machine.

Split tensile strength tests evaluated resistance against indirect tension. Flexural strength was measured using beam specimens subjected to two-point loading. The failure patterns were recorded and analyzed.

Data analysis was conducted to compare mechanical properties across different fiber dosages. Statistical evaluation ensured reliability of results. The optimal fiber percentage was determined based on overall performance improvement.

IV. EXPERIMENTAL SETUP

The experimental program included preparation of four concrete mixes: control mix and three fiber-reinforced mixes. The water-cement ratio was maintained constant to ensure consistency. Aggregates were tested for grading and specific gravity before mixing.

Steel fibers of 30 mm length and polypropylene fibers of 12 mm length were used. Mixing was performed in a mechanical mixer to ensure uniform dispersion. Care was taken to avoid fiber balling during mixing.

Specimens were cured in water tanks for 28 days. Compressive strength cubes of 150 mm size were tested as per IS standards. Beam specimens of 100×100×500 mm were used for flexural testing.

Testing equipment was calibrated before experiments. Load was applied gradually until failure. The maximum load values were recorded.

Crack patterns and failure modes were visually inspected. Comparative analysis was conducted between control and fiber mixes. Observations were documented systematically.

V. RESULTS AND DISCUSSION

The compressive strength results indicate moderate improvement with fiber addition. While fibers primarily enhance tensile and flexural properties, slight gains in compressive strength were observed. At 1.0% fiber dosage, the maximum compressive strength increase was recorded. Beyond this dosage, marginal reduction in strength was observed due to workability issues. The fiber bridging mechanism delayed crack propagation. This resulted in improved post-peak behavior compared to brittle failure in conventional concrete. The improved confinement effect contributed to better load distribution.

Split tensile strength showed significant improvement with increasing fiber content. The 1.5% fiber mix exhibited the highest tensile strength enhancement compared to control mix. Fibers effectively resisted crack widening under tensile stress. The energy absorption capacity increased noticeably. Failure was gradual rather than sudden. This demonstrates improved ductility in fiber-reinforced specimens. The crack width reduction enhances long-term durability.

Flexural strength improved substantially due to fiber reinforcement. Beam specimens displayed increased load-carrying capacity and delayed crack initiation. The hybrid fiber system showed better performance than single fiber systems. Fibers transferred tensile stress across cracks, maintaining structural integrity. The enhanced flexural behavior makes FRC suitable for slabs and pavements.

Overall results confirm that optimized fiber dosage improves mechanical performance significantly. However, excessive fiber content may reduce workability and uniform distribution. Therefore, balanced mix design is critical. The experimental findings validate the suitability of fiber-reinforced concrete for high-performance structural applications.

VI. CONCLUSION

The study evaluated the mechanical behavior of fiber-reinforced concrete for high-performance applications. Results demonstrated significant improvement in tensile and flexural strength with fiber inclusion.

Fiber reinforcement enhanced ductility, crack resistance, and energy absorption capacity. Optimal performance was achieved at 1.0–1.5% fiber content.

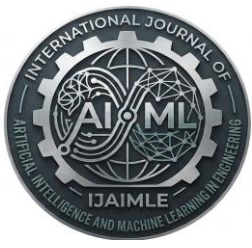

The research confirms that fiber-reinforced concrete is suitable for structures requiring improved durability and load-bearing capacity. Proper mix design ensures balanced mechanical properties.

FUTURE SCOPE

Future research may focus on hybrid fiber optimization, long-term durability studies, impact resistance analysis, and incorporation of sustainable materials such as fly ash and silica fume.
